As an extensively characterized II-VI wide bandgap semiconductor, zinc sulfide has been of significant interest for a long time due to its promising applications in various fields, including optical ceramics, phosphors, quantum dots, photocatalysts, and sensors [1–4]. When doped with transition metals and rare earth elements, ZnS can exhibit a wide range of luminescence behaviors in the visible and infrared regions [5–9]. In addition, due its exceptional performance as a material for room-temperature tunable solid state laser gain media in the mid-IR region, transition metal doped ZnS has inspired a tremendous amount of interest for researchers in past decades.

In 1996, researchers at Lawrence Livermore National Laboratory demonstrated the potential of divalent transition metal doped zinc chalcogenides as materials for mid-IR laser applications [10]. Various divalent transition metals (Co2+, Ni2+, Fe2+ and Cr2+) were doped into ZnS/ZnSe/ZnTe hosts, and their room temperature mid-IR lasing performances were examined. It was determined that the tetrahedral substitution sites, rather than the octahedral sites, are more favorable doping sites for transition metals in the zinc chalcogenides. The tetrahedral coordination of dopants might contribute to the observed intense low-energy transitions, due to small crystal field splitting. Among the Zn chalcogenides, Cr2+ doped ZnS/ZnSe showed exceptionally strong room-temperature absorption and emission in the mid-IR region. In addition, temperature-dependent lifetime measurements indicated that these materials revealed high (close to 80 and 100% for Cr:ZnS and Cr:ZnSe, respectively) luminescence quantum yield at room temperature due to weak non-radiative relaxation process [1,2]. It was demonstrated that Cr2+ doped ZnS/ZnSe crystals were the most promising candidates for room-temperature tunable mid-IR laser applications. Since then, chromium doped ZnS has attracted more and more extensive attention.

Mirov et al. have conducted tremendous research on the lasing performances of Cr2+:ZnS materials [11–14]. It has been reported that they applied chemical vapor transport (CVT) methods followed by thermal diffusion to fabricate Cr2+:ZnS transparent ceramic microchips with desirable lasing performances (optical and slope efficiency) [15]. It was also demonstrated by Wang et al. that Cr2+:ZnS thin films with promising properties for mid-IR applications could be prepared by pulsed laser deposition [16]. In addition, Martyshkin et al. investigated and demonstrated the effective photoluminescence and lasing properties of Cr2+:ZnS nanoparticles in the mid-IR region [17]. Meanwhile, by using Cr:ZnS single crystals, Tolstik et al. obtained Kerr-Lens passive modelocked Cr:ZnS femtosecond lasers, with distinguished pulse duration and energy [18,19]. The output characteristics of Kerr-lens-mode-locking were significantly improved in [20–22] with the use of Cr:ZnS polycrystalline gain media. Besides studying the lasing performance of Cr2+:ZnS, a significant amount of research has been conducted towards understanding the material, including the theory surrounding its crystal field splitting and local structure, as well as its potential applications in other fields such as cathodoluminescence and solar cell applications [23–26].

The most commonly reported method to fabricate Cr2+:ZnS transparent materials for laser applications is CVT method followed by thermal diffusion [27]. In addition, based on the method employed to process ZnS transparent ceramics, CVD combined with hot isostatic press (HIP) has also been used to prepare polycrystalline ZnS host ceramics prior to the thermal diffusion of Cr2+ ions [28]. However, these
methods are expensive and time-consuming, and have poor repeatability. As a common consolidation method, it is well known that hot pressing has been proven to be an effective and viable way to prepare various optically transparent non-oxide and oxide ceramics, such as ZnS, CaF₂, Y₂O₃, Li₂O₃, and MgAl₂O₄ [29–36]. It has also been demonstrated that Cr²⁺:ZnSe transparent ceramics with suitable properties for laser applications can be fabricated via hot pressing [37]. However, few studies have been reported on the hot pressing of Cr²⁺:ZnS transparent ceramics.

In the present study, Cr²⁺:ZnS IR transparent ceramics were fabricated via high vacuum hot pressing (VHP) using homogeneous ZnS powders synthesized using a wet chemical precipitation route, which were subsequently mixed with commercially sourced Cr₂S₃ powders. It was determined that the sintered Cr²⁺:ZnS ceramics were primarily composed of cubic sphalerite phase, with hexagonal wurzite as a minor phase. The ceramics were studied using SEM, and found to be well-consolidated and highly dense. The spectroscopic properties of the material were characterized to investigate the mid-IR absorption and photoluminescence behavior induced by doping with Cr²⁺.

The synthesis of ZnS powders was performed through a facile colloidal processing method, which was reported in our previous studies [31]. Aqueous solutions of thiourea (TAA, ≥ 99.0%, Sigma Aldrich) and Zn(NO₃)₂·6H₂O (≥99.0%, Sigma Aldrich) with stoichiometric ratios of Zn:S were mixed together by stirring, and HNO₃ (70%, Sigma Aldrich) was added to the mixed solution to adjust pH to 2. The solution was then heated in a hot water bath to encourage particle growth. After sufficient time, the suspension of ZnS colloids was cooled in an ice water bath to halt particle growth. The precipitates were then washed by both DI water and ethanol (Reagent alcohol, 100%, Decon) to remove reaction residues, and then dried in an oven in air. The precipitates were then finely ground and mixed with an addition of 0.1 mol% Cr₂S₃ (99%, Alfa Aesar) in an agate mortar and pestle. The mixed powders were then heated at 900 °C for 4 h in flowing argon to prepare for sintering. The ceramic samples were prepared for VHP by loading the powders into a graphite die with a diameter of 10 mm, with layers of graphite foil (thickness of 0.5 mm) used to separate the sample powders from the punches. The powders were consolidated at 1000 °C for 2 h under a uniaxial pressure of 50 MPa under a vacuum of 10⁻⁵ mbar (OFT-1200X-VHP4, MTI).

The phase composition of the sintered Cr²⁺:ZnS ceramics was determined using XRD (Bruker D2 PHASER) with Cu Kα (λ = 0.154 nm) radiation at a voltage of 30 kV and a current of 10 mA. Measurement conditions of 0.03° 2θ step size and 0.2 s count time were employed over a measurement range of 10–75° 2θ. The morphological and structural features of the Cr:ZnS powders and sintered ceramics were investigated by SEM (FEI Quanta 200) at an accelerating voltage of 20 kV. Archimedes method density measurements were adopted to determine the density of the as-sintered ceramics. The IR transmittance of the polished pellet was measured using FTIR (Nicolet 6700, Thermo Fisher). Photoluminescence spectra and kinetics characterizations were performed using an acousto-optically Q-switched Er:YAG laser under an excitation at 1.645 μm with ~60 ns pulse duration. Photoluminescence spectra were collected by using a monochromator (Acton Research ARC-300i). A Thorlabs PDA 20H PbSe detector, in addition to a fast PVI-3TE-5 (HgCdTe, VIGO systems) detector with a response time of ~200 ns were employed for signal detection. A polycrystalline Cr²⁺:ZnS sample with a chromium concentration of 8·10¹⁸ cm⁻³, fabricated by a post-growth thermal diffusion method [12], was used for the comparison of optical properties with the Cr²⁺:ZnS ceramics.

Fig. 1(a) shows the SEM image of the synthesized ZnS powders mixed with a 0.1 mol% addition of Cr₂S₃ powders. The powders appear to be composed of well-dispersed, homogeneous, spherical particles with a size of approximately 100–200 nm, the small size of which is attributed to the use of both hot and cold water baths to achieve better control of particle growth during colloidal processing. The microstructure of the thermally etched surface of the polished Cr²⁺:ZnS ceramics is shown in Fig. 1(b). It can be observed that the VHP-consolidated ceramics have an average grain size of about 1–2 μm and is highly dense, likely due to the homogenous morphology of the raw powders and the effectiveness of applied VHP technique. The relative density was measured to be 98.8%, which is in agreement with SEM observations of a highly consolidated microstructure. Fig. 1(c) displays the XRD pattern of the Cr²⁺:ZnS ceramics consolidated via VHP. The sample is composed of a mixture of mainly cubic sphalerite (JCPDS no: 65-5476; F-43 m; a = 5.40 Å) with a small amount of hexagonal wurzite (JCPDS no: 02-1310; P63mc; a = 3.82 Å, c = 6.25 Å). In addition, no Cr₂S₃ impurity peaks can be detected in the XRD measurement because of the low added level of Cr₂S₃. Due to the high surface energy of the small particles of the raw powders, during consolidation the Cr²⁺:ZnS ceramics experience an early phase transition from the cubic phase to hexagonal phase at 1000 °C, which is lower than the reported phase transition temperature of 1020 °C.

Fig. 2(a) shows the IR transmittance curve of a polished Cr²⁺:ZnS ceramic pellet, obtained by FTIR measurement over a wavelength range of 2.5–16.0 μm. Due to the effective consolidation via VHP, the Cr²⁺:ZnS polycrystalline ceramic sample exhibits high transmittance in the IR region, with a maximum transmittance of 67% at 11.6 μm, while the theoretical maximum transmittance according to the Fresnel equations is 75% in the IR range. It is important to note that the transmission curve shape near the IR edge is very similar for the VHP-consolidated ceramic sample and the polycrystalline sample fabricated via the post-growth thermal diffusion method. The reduced transmission observed in the VHP-consolidated ceramic sample in the near-IR spectral range is likely due to scattering effects within the ceramic. As can be observed from the inset photo, the sample is translucent even in the visible region, with the green color of the sample believed to result from the incorporation of Cr³⁺ ions into the ZnS lattice. Based on comparison of spectra from measurement of the samples and measurement of the ambient atmosphere, it is determined that the absorption peaks in the 3.2–7.0 μm range are due to atmospheric absorptions. Specifically, the absorption bands between 3.4, 3.5 and 4.2 μm are attributed to water adsorbed from the atmosphere, and the small peaks at 5.7, 6.2

Fig. 1. (a) SEM image of the synthesized ZnS powders mixed with 0.1 mol% Cr₂S₃ powders. (b) SEM image of the thermally etched surface of the VHP-sintered Cr²⁺:ZnS ceramics. (c) XRD pattern of the Cr²⁺:ZnS ceramics consolidated via VHP.
and 7.0 μm correspond to the C=O stretching modes of CO2 absorbed from the ambient atmosphere. ZnS characteristic vibrations lead to the band at 15.2 μm [9]. In addition, the absorption peak at 9.1 and 10.9 μm can be probably attributed to ZnS precursor residuals in the colloidal processing route or carbon contamination from graphite during the VHP process [30,31].

The near-IR transmittance curve of the sample is shown in Fig. 2 (b). Dotted line shows the baseline from the FTIR measurement of the ambient atmosphere. As can be determined from the transmittance plot, the VHP-sintered ceramic sample features a very strong scattering effect. It is important to note that the broad band at 1690 nm corresponds to the ground state to the excited state electronic transition from the cubic tetrahedral crystal splitting of the 3d-levels of Cr2+ (3d4) in ZnS [40]. In addition, as discussed in the aforementioned XRD analysis, both the cubic ZnS sphalerite phase and the hexagonal ZnS wurtzite phase are present in the ceramic. The difference in crystal structure and symmetry of these two phases may lead to polarization dependence of fluorescence [41], which in turn results in the asymmetric photoluminescence band shown in the emission spectrum [42,43].

Further characterization of the VHP-sintered Cr2+:ZnS ceramic sample’s mid-IR optical behaviors was performed to investigate the IR photoluminescence emission and corresponding emission kinetics of the Cr2+:ZnS. Fig. 3 (a) shows the room-temperature non-calibrated IR photoluminescence spectrum of the VHP-sintered ceramic under 1645 nm excitation. The sample exhibits the characteristic Cr2+ IR photoluminescence band from 2000 nm to 2200 nm, which is attributed to the 3E → 3T2 electronic transition, as a result of the cubic tetrahedral crystal splitting of the 3d-levels of Cr2+ (3d4) in ZnS [40]. In addition, as discussed in the aforementioned XRD analysis, both the cubic ZnS sphalerite phase and the hexagonal ZnS wurtzite phase are present in the ceramic. The difference in crystal structure and symmetry of these two phases may lead to polarization dependence of fluorescence [41], which in turn results in the asymmetric photoluminescence band shown in the emission spectrum [42,43].

Further characterization of the VHP-sintered Cr2+:ZnS ceramic sample’s mid-IR optical behaviors was performed to investigate the IR photoluminescence emission and corresponding emission kinetics of the Cr2+:ZnS. Fig. 3 (a) shows the room-temperature non-calibrated IR photoluminescence spectrum of the VHP-sintered ceramic under 1645 nm excitation. The sample exhibits the characteristic Cr2+ IR photoluminescence band from 2000 nm to 2200 nm, which is attributed to the 3E → 3T2 electronic transition, as a result of the cubic tetrahedral crystal splitting of the 3d-levels of Cr2+ (3d4) in ZnS [40]. In addition, as discussed in the aforementioned XRD analysis, both the cubic ZnS sphalerite phase and the hexagonal ZnS wurtzite phase are present in the ceramic. The difference in crystal structure and symmetry of these two phases may lead to polarization dependence of fluorescence [41], which in turn results in the asymmetric photoluminescence band shown in the emission spectrum [42,43].

Further characterization of the VHP-sintered Cr2+:ZnS ceramic sample’s mid-IR optical behaviors was performed to investigate the IR photoluminescence emission and corresponding emission kinetics of the Cr2+:ZnS. Fig. 3 (a) shows the room-temperature non-calibrated IR photoluminescence spectrum of the VHP-sintered ceramic under 1645 nm excitation. The sample exhibits the characteristic Cr2+ IR photoluminescence band from 2000 nm to 2200 nm, which is attributed to the 3E → 3T2 electronic transition, as a result of the cubic tetrahedral crystal splitting of the 3d-levels of Cr2+ (3d4) in ZnS [40]. In addition, as discussed in the aforementioned XRD analysis, both the cubic ZnS sphalerite phase and the hexagonal ZnS wurtzite phase are present in the ceramic. The difference in crystal structure and symmetry of these two phases may lead to polarization dependence of fluorescence [41], which in turn results in the asymmetric photoluminescence band shown in the emission spectrum [42,43]. Fig. 3 (b) shows the IR photoluminescence kinetics of the VHP-sintered Cr2+:ZnS sample measured at room temperature under 1645 nm excitation. The red curve shows the detector response time measured at the excitation

\[
\alpha = -\ln(T)/d
\]

(1)

where \(\alpha\) is the active absorption coefficient, \(T\) corresponds to the normalized transmittance ratio, and \(d\) is the thickness of the sample (0.07 cm). Here, we can estimate \(T\) to be 0.88, based on comparison of the actual measured transmittance at 1690 nm with the estimated baseline of the transmittance curve between 1400 nm and 2000 nm. After obtaining the active absorption coefficient at 1690 nm, the concentration of Cr2+ can be estimated by the following relation:

\[
N = \alpha/\sigma
\]

(2)

where \(N\) is the concentration of the ion, and \(\sigma\) refers to the absorption cross-section. It has been reported that the absorption cross-section of Cr2+:ZnS at 1690 nm is 1.0 \(\times 10^{18}\) cm\(^2\) [39]. Thus, the Cr2+ concentration can be calculated as 1.8 \(\times 10^{18}\) cm\(^{-3}\) (sufficient for laser materials). However, the concentration is much smaller than the total concentration of Cr originally introduced into the material, which suggests that the incorporated Cr ions may have different valence states other than 2+. Due to the reducing nature of the high vacuum and carburizing environment due to the presence of graphite in the VHP chamber, some Cr3+ ions from the added Cr2S3 are reduced to Cr2+ ions, which are then incorporated into the ZnS host lattice, but a portion of the Cr3+ ions from the Cr2S3 may still persist in the material. In addition, it is also revealed by a preliminary X-ray photoelectron spectroscopy characterization that there are some mixed valence states of Cr ions including 2+ and 3+ within the VHP-sintered ceramic. Future research is required to determine the location and valence states of the chromium ions in VHP-sintered Cr:ZnS ceramics.
wavelength for comparison. From the blue fitted \( \text{Eq. (3)} \) exponential decay curve shown in the spectrum, it is revealed that the sample exhibits a single exponential decay process with a lifetime of \( \tau = 5.5 \mu s \), which is consistent with previously reported decay times of the \( \text{Cr}^{2+} \rightarrow \text{E} \rightarrow \text{T}_{2} \) electronic transition in \( \text{Cr}^{2+}:\text{ZnS} \) [38].

\[
I(t) = A \exp(-t/\tau)
\]

where \( I(t) \) refers to the time-dependent luminescence intensity, \( A \) is a pre-exponential weight factor, and \( \tau \) corresponds to the actual time, and \( \tau \) is the decay time. This further demonstrates that the \( \text{Cr}^{2+} \) ions are tetrahedrally coordinated in the VHP-sintered \( \text{Cr}^{2+}:\text{ZnS} \) ceramic.

In summary, \( \text{Cr}^{2+}:\text{ZnS} \) IR transparent ceramics (67% transmittance at 11.6 \( \mu \)m) was successfully fabricated via vacuum hot pressing by consolidating colloidally processed \( \text{ZnS} \) powders mixed with commercially sourced \( \text{Cr}_{2}\text{S}_{3} \) powders. The \( \text{Cr}^{2+}:\text{ZnS} \) ceramics were determined to be primarily composed of cubic \( \text{ZnS} \) sphalerite phase, with hexagonal \( \text{ZnS} \) wurzite as a minor phase. It was demonstrated that the well-dispersed and homogenous morphology of the raw powders combined with the effects of VHP led to highly effective consolidation of the \( \text{Cr}^{2+}:\text{ZnS} \) powders into high-transparency ceramics. IR absorption analysis demonstrated that \( \text{Cr}^{2+} \) ions were incorporated into the \( \text{ZnS} \) lattice, and the concentration of \( \text{Cr}^{2+} \) in the VHP-sintered \( \text{Cr}^{2+}:\text{ZnS} \) ceramic was estimated to be \( 1.8 \times 10^{18} \text{ cm}^{-3} \). Characterization of the IR photoluminescence emission and kinetics of the VHP-sintered ceramic revealed the corresponding \( \text{E} \rightarrow \text{T}_{2} \) characteristic bands of \( \text{Cr}^{2+} \) in \( \text{ZnS} \), and further confirmed the existence of tetrahedrally coordinated \( \text{Cr}^{2+} \) within the \( \text{ZnS} \) host lattice. Further studies focused on decreasing scattering effects in VHP-sintered \( \text{Cr}^{2+}:\text{ZnS} \) are required to improve the optical performance of the material to increase its suitability for mid-IR laser applications.
